

Energy storage profit calculation formula

How do you calculate energy price for charging in year N?

To simplify the equation, let $E_{price n}$ be the energy price for charging in year n, described by $E_{price n} = e_{price} (1 + r_{ep})^n$.

How do you calculate nameplate capacity?

For the following equations, remember the nameplate capacity is equal to the number of kilo-watt hours that are discharged per n-cycle. In the context of determining the cost of a project that will be charged and discharged many times, it is more useful to normalize the costs to the energy discharged per cycle.

How much will LCOE cost a second set of energy storage investments?

This could be a mistake though, because there is no more curtailed solar to charge the devices, which means that the LCOE for the second set of energy storage investments would be \$0.04/kWh plus \$0.06/kWh from charging with existing, dispatchable generators.

How do you calculate overnight capital costs?

As such, the overnight capital costs will be normalized to the amount of energy discharged per cycle at the rated depth of discharge. This yields units of $\text{dollars} / \text{kWh} / \text{cycles} = \text{dollars} * \text{cycles} / \text{kWh}$.

How profitable is BESS for Energy Arbitrage grid applications?

In fact, as reported by the CAISO special report on battery storage, the largest positive revenue comes from day-ahead market energy schedules. For this reason, it is crucial to properly analyze the profitability of using BESS for energy arbitrage grid applications.

How do you calculate yearly cumulative revenue component R_{cum} ?

As defined in Eq. (9), the yearly cumulative revenue component R_{cum} is obtained by multiplying the LMP hourly energy price LMP_t with the BESS discharge power $P_{dh, BESS, t}$ for reach time step t , taking into account the BESS discharge dynamic efficiency $\eta_{BESS, dh, t}$ and the self-discharge losses occurring during the discharge phase $\eta_{self, dh}$.
